We report the fabrication of devices in which one single-walled carbon nanotube spans a barrier between two fluid reservoirs, enabling direct electrical measurement of ion transport through the tube. A fraction of the tubes pass anomalously high ionic currents. Electrophoretic transport of small single-stranded DNA oligomers through these tubes is marked by large transient increases in ion current and was confirmed by polymerase chain reaction analysis. Each current pulse contains about 107 charges, an enormous amplification of the translocated charge. Carbon nanotubes simplify the construction of nanopores, permit new types of electrical measurements, and may open avenues for control of DNA translocation.

We report the use of single-walled carbon nanotubes (SWCNTs) as nanopores for analyzing molecular transport properties. Nanopores are orifices of molecular diameter that connect two fluid reservoirs. At this length scale, the passage of even a single molecule generates a detectable change in the flow of ionic current through the pore (1, 2). They can be used as single-molecule Coulter counters and form the basis of proposed new approaches to DNA sequencing (3). The first nanopore devices were based on pore proteins (4–7), but more recently pores have been fabricated by drilling (and sometimes partially refilling) solid-state materials (8–12). Nanochannels have been formed by etching silicon nanowires (13), and channels with one nanoscale dimension have been etched into glass (14) or quartz (15).

Carbon nanotubes are obvious candidates for the fabrication of nanopore structures. Pressure-driven gas, water, and ion transport has been recorded through membranes composed of many multiwalled carbon nanotubes (16) or double-walled carbon nanotubes (17). These experiments showed that the water flow rate is greatly enhanced inside the tube, an effect confirmed by molecular dynamics simulations (18). DNA has been passed through a 100-nm diameter carbon nanotube (19) and 50-nm-wide hydrophilic channels (13). It seems counterintuitive that hydrophilic DNA would enter the hydrophobic interior of a SWCNT, but simulations show that both RNA (20) and DNA (21) will translocate through 1.5- to 2-nm diameter tubes. The simulations were carried out using very large electric fields (tenths of a volt per nm) to generate observable motion on the simulation time scale. This result leaves open the possibility that some measurable translocation might occur at the much smaller fields that could be implemented in the laboratory. Here, we report direct measurement of this translocation.

We have made a device in which one SWCNT spans a barrier between two fluid reservoirs [see Fig. 1 and Supporting Online Material (22)]. Relative to CNT membranes (16, 17), this arrangement makes it possible to detect signals from the translocation of a single molecule and to correlate
transport with the properties of individual SWCNTs. We grew well-separated SWCNTs on the surface of oxidized silicon wafers and formed fluid reservoirs along the path of chosen tubes with electron-beam lithography. A scanning electron microscopy (SEM) image of a device at this stage is shown in Fig. 1A, where the SWCNT is just visible on each side of the barrier. An oxygen plasma was used to remove the exposed parts of the SWCNT, leaving the SWCNT under the barrier intact (fig. S4I) (22, 23). The fluidic pathway was completed by placing a poly(dimethylsiloxane) (PDMS) cover on top of the chip (Fig. 1B).

Each chip also contained control devices lacking the bridging SWCNT (22) to check the integrity of the barrier, including devices with unopened SWCNTs. We used a mild plasma treatment such that 100% of the devices lacking CNTs did not leak (fig. S5), although this approach resulted in a large fraction of tubes that were not opened (20%), as determined by SEM imaging (fig. S4F). The fluid reservoirs were filled with 1 M KCl, and Ag/AgCl electrodes (BASI MF-2078) were used to measure the conductance across the reservoirs connected by the SWCNT. The devices passed current if, and only if, they were spanned by a SWCNT that was opened (Fig. 1C), so the interface between the tube and the poly(methyl methacrylate) (PMMA) does not appear to provide a leakage path. This conclusion was verified by chemically tethering poly(ethylene glycol) molecules to one or both ends of the CNTs. The current was reduced in one direction of bias when the tube was modified at one end, and in both directions of bias when the tube was modified at both ends (fig. S6).

Table 1. Relation of ionic conductance with electrical properties (Vf is the threshold voltage for semiconducting tubes). These measurements do not discriminate between metallic SWCNTs and bundles containing a metallic tube, but most of the tubes are single-walled (30). Raman scattering was used to determine diameters marked * and confirm electronic properties marked †. The tube marked ‡ was not translocated DNA.

Fig. 2. Ion transport in the subset of SWCNTs with high ionic conductance. (A) Current versus voltage applied to Ag/AgCl reference electrodes for a 2-μm long, 1.7-nm diameter SWCNT for various concentrations of KCl electrolyte as marked. The solid lines are simulated as described in the text. (B) Ionic conductance as a function of salt concentration. The red line is a fit to the e^m dependence suggested by molecular dynamics simulations. We found 0.33 < m < 0.4 in three different tubes. The blue line shows the salt dependence of conductance measured in a planar nanopore (27). (C) In this subset of tubes, current at 1 M KCl is better related to diameter (green squares). The red dashed lines show simulations for excess charge densities of 2, 3, and 4 M.

an electrode contacting the SWCNT directly revealed that electrochemical currents were negligible for the potentials used here (fig. S11).

To look for clues to a mechanism for the large ionic currents, we used molecular dynamics simulations coupled with solutions of the Poisson-Nernst-Planck equation for transport in the SWCNT and the outside reservoirs (22). The flow rate of water is greatly enhanced inside SWCNTs (17), but the molecular dynamics simulations showed that the electrophoretic mobility of ions is similar to that in the bulk electrolyte. However, the selective filtering of anions or cations owing to charged end groups (26) can result in a net excess concentration, \( n \), of one charge inside the tube. This charge will, in turn, drive an electroosmotic current. Molecular dynamics simulations further showed that both water and ions flow with an electroosmotic velocity, \( v \), given by \( v \propto n^{0.74} \) for a (10,10) SWCNT. Both anions and cations are driven in the same direction by an extremely large electroosmotic flow, but only the charge imbalance inside the tube results in a net ionic current proportional to \( n \); that is, \( \propto n^{1.74} \). The mechanism of charge accumulation is complex and involves both charged end groups and the electronic properties of the SWCNT, and we have not yet developed a quantitative model for it (see fig. S12 for further evidence of the role of charged end groups).

However, current-voltage curves obtained at different salt concentrations in the reservoirs, \( c \), can be fitted if \( n = 3.31 \times 10^{0.22} \) M (Fig. 2A). This result is equivalent to an ionic conductance that varies as \( c^{0.39} \), shown by the red curve passing through the measured data in Fig. 2B. This dependence on concentration is quite different from the linear dependence expected for a tube of electrolyte or the saturation at low salt observed for a planar nanopore carrying a surface charge (27).

In contrast to the full set of devices, the subset with anomalously high conductance does show some relation between conductance and tube diameter (Fig. 2C, green squares). The red dashed lines show simulated values of ionic conductance as a function of diameter for \( n = 2, 3, \) and \( 4 \) M. The measured data can be accounted for by assuming that variability in the charge of end groups leads to some variability in \( n \).

Although it might be instructive to study the translocation of simpler polyelectrolytes as a prelude to the study of DNA, methods such as dye-labeling are much less sensitive than polymerase chain reaction (PCR) for detecting and counting small numbers of molecules. To test for DNA translocation of SWCNTs, we used 60-nt and 120-nt DNA oligomers with sequences that were predicted to be relatively free of secondary structure, with forward and reverse primers chosen to have high melting temperatures to minimize primer dimers and false priming (22). Devices were characterized by measuring current flow with 1 or 2 M KCl alone, and then a DNA solution [1 or 2 M KCl, 1 mM phosphate-buffered saline (PBS), pH 7] was flowed into the input reservoir side. A control sample was collected from the output reservoir to check for DNA contamination, and a positive bias was then applied to the output side of the device. In the subset of high current tubes, we first observed a slow increase in the background current (Fig. 3A, A and B; data are for 0.1 nM DNA). After a time, which varied from a few to tens of minutes, depending on the DNA concentration in the input reservoir, large transient increases in current were observed. These “spikes” were accompanied by large fluctuations in the background current (Fig. 3C). The spikes disappeared when the polarity of the bias across the tube was reversed and reappeared when the original bias (positive on the output side) was restored. Quantitative PCR (QPCR) (22) showed that DNA was translocated in devices manifesting these large spikes. Translocation occurred only in tubes with conductances (before DNA addition) of >2 nS (Fig. 1C). Some devices that showed instabilities in the background but no large current spikes (Fig. 3F) gave negative PCR results. We also tested for transloc-

![Fig. 3.](image-url) Ion current signals of DNA translocation. (A) Current (2 M KCl, 1 mM PBS, pH 7) before DNA addition. (B) After DNA addition, current slowly increases. (C) 5 min after addition of 0.1-nM 60-nt DNA, large positive current spikes appear. These spikes are followed by a drop in baseline over a period of a second or so and then by a gradual rise leading to the next spike. (D) Representative data from another tube (also 60-nt DNA), with the distribution of currents shown in (E). The DNA causes large changes in baseline in addition to the spikes. (F) Data from a tube that showed both a current increase on DNA addition and baseline fluctuations but no spikes. No translocation was detected by PCR. The insets in (C) and (F) show the fluorescence signal from double-stranded DNA dye labels as a function of the PCR cycle number for samples collected from these particular runs.

**Table 2. Results of QPCR tests for translocation in tubes with conductance >2 nS that gave uncontaminated control signals (data from four other devices that showed contamination in the control sample were rejected). Errors in spike count reflect the consequences of different cut-off criteria for selecting spikes. Errors in the molecule count were dominated by uncertainties in the filter recovery efficiency, except for the data marked *, which were calibrated with a second oligomer.**

tion in “failed” control devices (i.e., lacking the CNT and deliberately overetched) that displayed leakage current. A few with very large leakage current showed evidence of DNA in the output well, but none displayed spikes, regardless of the magnitude of the leakage current. Thus, the spikes signal translocation of DNA through the SWCNTs.

QPCR also provides a measure of the number of molecules collected. We collected small samples of fluid from the output reservoir by flushing the system through with excess buffer and concentrated the solution using a Microcon YM-10 centrifugal filter so that we could reduplicate with PCR buffer. The filter losses were found to be highly variable, more so at low DNA concentrations, and account for much of the stated uncertainty in our results. We calibrated the PCR reaction with known amounts of DNA and, for two data points, calibrated filter losses by adding a known amount of a second sequence (with orthogonal primers) and carrying out a PCR analysis of both the target and calibration samples. The final molecule count was corrected for filter losses and dilution during the sample collection. The various errors in these steps tend to underestimate the amount of DNA that translocated, so the final results are probably lower limits. PCR was limited to the first use of a device, and we rejected samples from chips that showed contamination in the control samples collected.

We were able to carry out PCR on samples collected from 12 devices that had a conductance >2 nS. Of these, four had DNA contamination in control samples, leaving the eight devices listed in Table 2. Two of these showed no spikes and yielded no PCR signal. The remaining six all appeared to pass more than one molecule per spike. In particular, tubes HL-4-1-36 and A136, for which the filter recovery was directly measured with a control sample, passed at least 30 to 40 molecules for each spike. It is possible that the tube fills entirely with DNA, the spike signaling the cooperative emptying (or possibly filling) of the tube. The uncertainties in the PCR measurement are too large to reveal any significant difference between the number of molecules per spike for the 60-nt sample (23, 13, 34, and 41) and the 120-nt sample (88 and 16), although the spike frequency was much lower in the two 120-nt runs, and the spike duration significantly longer (figs. S13 and S14).

Figure 4A shows data for the spiking rate as a function of bias for two different tubes passing 60-nt DNA. The spike rate increased with applied bias, and the two tubes showed different threshold biases for the onset of spikes (and hence translocation). For the 60-nt DNA, the spike amplitudes are about 5% of the baseline current (Fig. 4B), and their duration is between 3 and 100 ms, independent of applied bias, as long as it is above the threshold for translocation. The product of the spike duration and amplitude yields the charge contained in each spike (Fig. 4C). This is remarkably large, at about 1 pC or 10^12 electrons in each spike. Fan et al. explained positive charge spikes observed in nanochannels as a consequence of additional mobile ions brought into the channel by DNA molecules (13). Filling the tubes (2 μm long) with 100 (20 nm long) 60-nt DNA oligomers, each carrying 60 excess electronic charges would account for only 1 part in 10,000 of the observed charge in each spike. The spikes must originate with large changes in the polarization outside the tubes, much as observed in junctions between micro- and nanochannels (28). The charge accumulation caused by the asymmetrical current in the SWCNT might be the source of this polarization, but further modeling is required to shed light on this unusual signal.

The excess ionic conductance appears to be a characteristic of metallic tubes, and we have proposed a mechanism based on electroosmotic flow resulting from trapped charge. Tubes with high ionic conductance will transport DNA molecules, giving a distinctive and unexpectedly large electrical signal of translocation. This kind of nanopore combines a long channel (in which translocation velocity might be slowed) with an “integrated” electrode that might prove useful in new schemes for sequencing DNA by tunneling (3). The ability to select metallic SWCNTs of a desired diameter (29) may open the way for production of devices with particular pore sizes.
